5 **Abstract**

6 Network-based metrics are widely used to identify associations between compounds and diseases, as-
7 suming that proximity within a protein–protein interaction network reflects functional relevance. How-
8 ever, these metrics are often reported as Z-scores, which we demonstrate are fundamentally sensitive to
9 the number of targets a compound possesses. This dependency introduces a systematic bias where com-
10 pounds with broad polypharmacology appear statistically significant due to null distribution tightening
11 (the Law of Large Numbers) rather than physical network reachability.

12 Here, we systematically evaluate this bias using the human liver interactome and a controlled com-
13 parison of two constituents from *Hypericum perforatum*. We show that conventional proximity Z-scores
14 yield unstable rankings that reverse depending on network construction parameters. While a compound
15 with many targets may achieve a higher Z-score, it can remain physically more distant from the dis-
16 ease module than a compound with fewer, high-leverage targets. We resolve this by utilizing random
17 walk–based influence propagation and introducing a size-normalized metric: perturbation efficiency.
18 Our results show that influence-based rankings are stable across varied network thresholds and correctly
19 identify high-leverage modulators that proximity metrics miss. This study provides a methodological
20 template for identifying and correcting statistical artifacts in network medicine, enabling more reliable
21 risk assessment in complex biological systems.

22 **Keywords:** network propagation, proximity metrics, metric robustness, drug-induced liver injury,
23 polypharmacology, Z-score confounding, perturbation efficiency.

24 1 Introduction

25 Network-based prioritization is a cornerstone of modern systems biology and drug discovery, assuming
26 that the topological proximity between compound targets and disease genes within a protein–protein in-
27 teraction (PPI) network reflects functional relevance [1–4]. Because raw network distances are sensitive
28 to local topology and degree distribution, they are typically reported as Z-scores relative to degree-
29 matched null models. While these Z-scores are intended to quantify statistical significance, they are
30 fundamentally confounded by the number of targets a compound possesses. As the number of seed
31 nodes increases, the variance of the null distribution decreases (the Law of Large Numbers), leading to
32 deterministic significance inflation for compounds with broad polypharmacology. Identifying whether
33 such results reflect true biological influence, or whether they represent systematic artifacts of distance-
34 based inference, is essential for the reliability of network medicine.

35 Using the human liver interactome as a model system, we investigate this confounding effect through
36 a controlled comparison of two constituents from *Hypericum perforatum* (St. John’s Wort). These con-
37 stituents—Hyperforin and Quercetin—exhibit highly asymmetric target set sizes: Hyperforin possesses
38 10 validated targets, while Quercetin has over 60 [5–7]. This asymmetry provides a sharp stress test
39 for network metrics. Conventional proximity Z-scores predict greater disease-associated significance for
40 the broad-spectrum modulator, even when it is physically more distant from the disease module than the
41 high-leverage modulator. This reversal indicates that proximity-based prioritization is unstable across
42 network construction parameters and susceptible to sample-size artifacts.

43 Here, we evaluate the robustness of proximity-based and influence-based metrics for comparative
44 prioritization. We demonstrate that proximity Z-scores yield unstable, threshold-dependent rankings
45 driven by null-distribution tightening rather than physical reachability. To resolve this instability, we
46 utilize random walk–based influence propagation, which integrates over the entire network topology and
47 captures signal amplification through regulatory hubs [8]. We introduce a normalized metric, perturba-
48 tion efficiency, to account for target set size and ensure unbiased comparisons. Our results show that
49 influence-based propagation provides a stable, theoretically consistent framework for network pharma-
50 cology that correctly identifies high-leverage perturbations where traditional proximity metrics fail.

51 **2 Results**

52 **2.1 Proximity Z-scores are confounded by target set size**

53 We first established network context by quantifying target count and shortest-path proximity to 82 DILI-
54 associated genes (Figure 1). Quercetin engages 62 targets in the liver-expressed largest connected
55 component; Hyperforin engages 10. At STRING confidence ≥ 900 , Hyperforin targets are physically
56 closer to DILI genes ($d_c = 1.30$) than Quercetin targets ($d_c = 1.68$; Table 1). However, the proxim-
57 ity Z-scores yield the opposite ranking: Quercetin achieves $Z = -5.44$ ($p < 0.001$), while Hyperforin
58 achieves $Z = -3.86$ ($p < 0.001$). All reported associations survived Benjamini–Hochberg FDR correc-
59 tion ($q < 0.05$).

60 This discrepancy highlights a fundamental confounder in proximity Z-scores: the law of large num-
61 bers. As target set size increases, the variance of the null distribution decreases ($\sigma_{null} = 0.09$ for
62 Quercetin vs 0.24 for Hyperforin), inflating the significance of broader target sets despite greater phys-
63 ical distance. This statistical artifact suggests that Quercetin poses greater risk, whereas the physical
64 topology favors Hyperforin.

65 **2.2 Influence-based rankings are stable and resolve the confound**

66 Random walk with restart (RWR) stabilizes this ranking by integrating over all paths (Figure 2). Hyper-
67 forin achieves influence $Z = +10.12$ ($p < 0.001$); Quercetin achieves $Z = +4.55$ ($p < 0.001$; Table 1).
68 Unlike proximity, influence Z-scores correctly reflect the topological advantage of Hyperforin’s regula-
69 tory hub occupancy. The ranking remains consistent across topology-only and expression-weighted anal-
70 yses, demonstrating that influence propagation is less susceptible to sample-size artifacts than shortest-
71 path distance.

72 **2.3 Expression weighting refines the signal**

73 To assess whether the RWR signal persists under tissue-specific constraint, we applied expression-
74 weighted influence propagation (EWI), weighting transitions by destination-node liver expression (Fig-
75 ure 3).

76 The Z-score differential narrows but remains substantial under expression weighting: Hyperforin
77 $Z = +8.98$ ($p < 0.001$); Quercetin $Z = +5.79$ ($p < 0.001$). Hyperforin’s advantage is driven primarily
78 by the PXR–CYP master regulatory axis, which remains highly active in liver tissue (e.g., CYP3A4 at
79 335 TPM). Quercetin’s influence is moderated by its broad, diffuse target profile, which includes several

80 high-expression nodes (e.g., CFB at 1,115 TPM) that do not converge on a DILI effector hub.

81 **2.4 Normalizing for target count confirms Hyperforin's topological advantage**

82 To resolve the target-count paradox, we compared the average network influence of each individual
83 target, reframing polypharmacology as an efficiency problem rather than a coverage problem (Figure 4;
84 Table 2).

Compound	Targets	Eff. (RWR)	Eff. (EWI)	RWR Ratio*	EWI Ratio†
Hyperforin	10	0.1138	0.1330	—	—
Quercetin	62	0.0322	0.0493	—	—
Fold difference	—	—	—	3.5× (3.7×)	2.7× (2.8×)

86 *RWR Ratio: observed ratio (robust ratio in parentheses). †EWI Ratio: observed ratio (robust ratio in paren-
87 theses).

88 Each Hyperforin target contributes 3.7× more DILI-directed influence than each Quercetin target (robust ra-
89 tio). This disparity indicates that Hyperforin's target positions are substantially higher leverage than those of
90 Quercetin, achieving greater perturbation efficiency despite a 6-fold smaller target set.

91 **2.5 Bootstrap resampling excludes target-selection bias**

92 To rule out the possibility that Hyperforin's advantage arises from favorable target selection rather than strategic
93 network positioning, we performed bootstrap sensitivity analysis (Figure 5). 100 random 10-target subsets were
94 sampled without replacement from Quercetin's 62-target pool and scored by RWR.

95 Hyperforin's observed influence (0.1138) exceeds the entire bootstrap distribution from Quercetin (mean =
96 0.0308, 95% CI = [0.0160, 0.0542]; Table 3). The fold difference between Hyperforin and the bootstrap mean is
97 3.7×. This confirms that Hyperforin's advantage is not an artifact of target count; even when sampling equalized
98 subsets from Quercetin's pool, no configuration matches Hyperforin's influence.

99 **2.6 Ranking stability across network thresholds**

100 The influence ranking is stable across network confidence thresholds (Table 6). Hyperforin ranks first in all RWR
101 and EWI configurations at both ≥ 700 and ≥ 900 thresholds. Notably, the proximity ranking reverses between
102 thresholds: at ≥ 700 , Hyperforin is physically closer ($d_c = 0.60$ vs 1.34) and more "significant" ($Z = -6.04$ vs
103 -5.46). At ≥ 900 , Quercetin appears more "significant" ($Z = -5.44$ vs -3.86) despite being physically more dis-
104 tant (1.68 vs 1.30). This instability in proximity Z-scores—while influence rankings remain stable—demonstrates
105 that influence-based metrics are more robust to network construction parameters.

106 **2.7 Chemical similarity excludes structural confounding**

107 To exclude the possibility that Hyperforin's network signal reflects structural similarity to known hepatotoxins,
108 we performed chemical similarity analysis against the DILIrank reference set (Figure 6). Morgan fingerprints
109 (ECFP4) revealed that neither compound exceeds the 0.4 Tanimoto threshold for structural analog detection. No-
110 tably, Quercetin exhibits higher structural similarity to DILI reference drugs yet lower network influence, reinforc-
111 ing that the observed asymmetry is driven by network topology rather than chemical features.

112 **3 Discussion**

113 **3.1 Ranking stability and the Z-score confound**

114 The results of this study highlight a potential limitation in the use of network proximity Z-scores when comparing
115 compounds with asymmetric target set sizes. While proximity is a standard prioritization criterion, our analysis
116 demonstrates that its significance rankings can be influenced by the target count rather than topological distance
117 alone. As the number of targets increases, the variance of the null distribution decreases, which can lead to inflated
118 significance levels for compounds with broad polypharmacology. In our controlled comparison, this effect causes a
119 reversal of proximity-based rankings between network thresholds, failing to accurately reflect the physical distance
120 advantage of a high-leverage modulator.

121 Influence-based metrics (RWR and EWI) appear less sensitive to this particular artifact. By integrating over the
122 entire network topology, these methods capture signal propagation through regulatory hubs, providing rankings that
123 remain stable across different network construction parameters. This relative stability suggests that influence-based
124 propagation may offer a more robust framework for comparative network medicine, particularly in the presence of
125 incomplete or asymmetric pharmacological data.

126 The mechanistic explanation for this robustness is that RWR integrates over *all* paths, capturing how signals
127 amplify through hubs like PXR and AKT1. Shortest-path proximity, by contrast, is a descriptive metric for min-
128 imum reachability; treating it as an inferential surrogate for functional impact conflates topological context with
129 biological consequence.

130 **3.2 Expression weighting as a biological constraint**

131 Expression-weighted influence (EWI) constrains signal propagation to liver-active nodes. By attracting signal to
132 highly expressed proteins (destination-node weighting), we ensure that the network propagation reflects tissue-
133 specific biology. Under this constraint, the Hyperforin advantage persists, demonstrating that its topological ef-
134 ficiency is not an artifact of an unconstrained PPI network but is supported by the expression profile of the liver.
135 Attenuation of signal is expected when walks are constrained to active pathways; the fact that the ranking remains
136 stable provides positive evidence for the biological relevance of the PXR axis.

137 **3.3 Perturbation efficiency vs. topological coverage**

138 By normalizing total influence for target set size (where the restart vector is already $|T|$ -weighted), we provide
139 a more balanced comparison of perturbation efficiency. Our results show that a single Hyperforin target exerts
140 3.7-fold more influence on the DILI module than a Quercetin target.

141 This efficiency claim is further validated by bootstrap sensitivity analysis. Even when sampling size-matched
142 10-target subsets from Quercetin’s pool, none reached the influence level achieved by Hyperforin. This demon-
143 strates that the advantage is not due to target count, but to the strategic network position of Hyperforin’s tar-
144 gets—specifically their convergence on the PXR master regulator and downstream CYP effectors.

145 **3.4 Mechanistic context: The PXR axis**

146 The stability of the influence ranking aligns with the well-characterized PXR–CYP master regulatory axis. Hyper-
147 forin’s primary target, NR1I2 (PXR), induces the expression of major xenobiotic metabolism enzymes including
148 CYP3A4 and CYP2C9 [6, 9]. In our network analysis, these effectors are part of the target set and the DILI
149 module, creating a high-connectivity hub structure that enables efficient propagation. Quercetin’s 62 targets, while
150 numerous, are distributed across redundant or peripheral pathways that do not converge on a regulatory bottleneck.
151 Furthermore, clinical evidence indicates that Quercetin is not associated with hepatotoxicity and may exhibit hep-
152 atoprotective properties [7, 10]. Recent experimental studies have corroborated that St. John’s wort exacerbates
153 hepatotoxicity through precisely this PXR-mediated bioactivation mechanism [11].

154 **3.5 Limitations**

155 Several limitations warrant consideration. First, network influence is a measure of topological reach and pertur-
156 bation potential, not a direct surrogate for toxicological outcomes. This model is dose-independent and does not
157 account for pharmacokinetics, binding affinity, or saturation kinetics. A high influence score indicates that a com-
158 pound’s targets are strategically positioned to modulate a disease module, but the actual biological effect depends
159 on the molecular mechanism of action (e.g., agonism vs. antagonism) and the kinetic context.

160 Second, while we demonstrate that proximity Z-scores are confounded by target set size, influence-based Z-
161 scores are not entirely immune to this effect. As the number of seed nodes increases, the variance of the null
162 distribution for influence sums also decreases, though less severely than for distance-based metrics. Critically,
163 our core claims do not rest on absolute Z-score comparisons. We demonstrate that influence-based *rankings* are
164 stable across network thresholds, while proximity rankings are not. We further resolve the size-dependence by
165 introducing perturbation efficiency (influence per target), which explicitly normalizes for target count and provides
166 a bias-corrected comparative metric.

167 Third, our case study is limited to a single botanical with two contrasting constituents. While this provides a
168 controlled minimal model, generalization to larger compound libraries will require further validation.

169 **3.6 Conclusions**

170 In this study, we utilized *H. perforatum* as a known toxicological model to validate the *reliability* of network
171 metrics; the biological ground truth (Hyperforin-mediated PXR activation) allowed us to confirm that influence
172 propagation correctly identifies high-leverage perturbations where proximity metrics fail. The methodological
173 conclusion is that proximity Z-scores are susceptible to sample-size confounding and should be used descriptively
174 rather than for comparative inference across compounds with differing target counts. Influence-based propagation,
175 combined with per-target normalization, provides a more stable framework that survives robustness checks and
176 aligns better with mechanistic reality.

177 More broadly, this work provides a methodological template for identifying and resolving metric artifacts
178 in network toxicology. By integrating signed edge weights and transcriptometric data, future iterations of this
179 framework could investigate phenotype-specific associations, linking topological influence on specific biological
180 sub-modules to discrete clinical outcomes.

181 **4 Methods**

182 **4.1 Data sources**

183 **4.1.1 Protein–protein interaction network**

184 Human protein–protein interactions were obtained from STRING v12.0 [12]. Combined confidence scores were
185 computed per STRING methodology (text mining, experiments, databases, co-expression, neighborhood, gene
186 fusion, co-occurrence). Only edges with combined confidence ≥ 900 (highest confidence tier) were retained. Raw
187 network: 11,693 genes, 100,383 edges.

188 **4.1.2 Liver expression data**

189 Gene expression data were obtained from the Genotype-Tissue Expression Project (GTEx) v8 [13]. Median tran-
190 scripts per million (TPM) values for liver tissue were extracted from the 2017-06-05 release (RNASeQCv1.1.9).
191 Genes with liver TPM ≥ 1 were retained. Result: 13,496 liver-expressed genes.

192 **4.1.3 Drug-induced liver injury gene set**

193 DILI-associated genes were obtained from DisGeNET [14] curated gene-disease associations. Query: UMLS
194 concept identifier C0860207 (Drug-Induced Liver Injury). Inclusion criterion: genes with curated evidence linking
195 to DILI. Raw DILI gene count: 127 genes.

196 **4.1.4 Hyperforin targets**

197 Hyperforin targets were curated from primary literature sources [6, 9]. Sources included studies of PXR activation,
198 CYP induction, and ABC transporter modulation. Raw target count: 14 proteins (Table 7).

199 **4.1.5 Quercetin targets**

200 Quercetin targets were retrieved programmatically from ChEMBL v31 [15] via REST API. Query: CHEMBL159
201 (Quercetin). Filter: human targets with experimentally validated bioactivity (IC_{50} , K_i , or $EC_{50} \leq 10 \mu M$). Raw
202 target count: 122 proteins.

203 **4.2 Target processing**

204 Protein identifiers were mapped to HUGO gene symbols using STRING info files and UniProt [16]. Non-human
205 proteins (mouse, rat, bacterial, viral) were excluded. Gene symbols were standardized (e.g., MDR1 → ABCB1).
206 Processed target counts: Hyperforin = 14, Quercetin = 87.

207 **4.3 Network construction**

208 The STRING network was filtered to genes with liver expression ≥ 1 TPM (GTEx v8). The largest connected
209 component (LCC) was extracted using NetworkX [17]. Compound targets and DILI genes not present in the LCC
210 were excluded. Final network: 7,677 nodes, 66,908 edges. Final target counts: Hyperforin = 10, Quercetin = 62.
211 Final DILI gene count: 82.

212 Five genes are targeted by both compounds: ABCG2, AKT1, CYP3A4, MMP2, MMP9. These were retained
213 in both target sets.

214 **4.4 Shortest-path proximity (descriptive)**

215 Mean minimum shortest-path distance from compound targets T to DILI genes D :

$$d_c = \frac{1}{|T|} \sum_{t \in T} \min_{d \in D} \text{dist}(t, d) \quad (1)$$

216 where $\text{dist}(t, d)$ is the unweighted shortest-path length in the LCC. Shortest-path proximity is a descriptive metric.
217 It was used to provide network context, not to test influence.

218 **4.5 Random walk with restart**

219 Influence propagation was quantified using random walk with restart (RWR), a global network propagation al-
220 gorithm that captures both direct and indirect associations by simulating the diffusion of signal from seed nodes

[3, 8]. Given an adjacency matrix \mathbf{A} , we define the column-normalized transition matrix \mathbf{W} as:

$$W_{ij} = \frac{A_{ij}}{\sum_k A_{kj}} \quad (2)$$

The steady-state probability vector \mathbf{p} is solved iteratively until convergence:

$$\mathbf{p}^{(k+1)} = (1 - \alpha)\mathbf{W}\mathbf{p}^{(k)} + \alpha\mathbf{p}_0 \quad (3)$$

where:

- $\alpha = 0.15$ is the restart probability (teleportation factor), ensuring the walk remains local to the seeds.

- \mathbf{p}_0 is the restart (seed) vector, with $p_0(i) = 1/|T|$ for $i \in T$ (targets) and 0 otherwise.

- Convergence is defined as the L_1 norm of the difference between successive iterations being $< 10^{-6}$.

All computations reached convergence within 100 iterations. The total influence I on the DILI module D is the sum of steady-state probabilities at disease nodes: $I = \sum_{d \in D} p(d)$.

4.6 Permutation testing and degree matching

To assess whether the observed influence I is significantly greater than what would be expected by chance, we performed permutation testing ($n = 1,000$). To account for the bias where high-degree nodes (hubs) naturally accumulate more influence, we utilized a degree-preserving sampling strategy. For each target $t \in T$, a random surrogate node was sampled from the network such that its degree k_{rand} was within $\pm 25\%$ of the original target's degree k_t . This ensures that the null distribution reflects the connectivity profile of the original target set. Random seeds were fixed to 42 for reproducibility. Z-scores were computed as $Z = (x_{obs} - \mu_{null})/\sigma_{null}$, and empirical P -values were derived from the null distribution.

4.7 Expression-weighted influence

Edge weights were modified by destination-node liver expression:

$$W'_{ij} = \frac{A_{ij} \cdot e_i}{\sum_k A_{kj} \cdot e_k} \quad (4)$$

where e_i is the normalized liver expression for gene i (GTEx v8 liver). Liver TPM values were log-transformed ($\log_2(\text{TPM} + 1)$) and min-max normalized to $[0, 1]$ across the network. A minimum expression floor of 0.01 was applied to ensure all nodes remained reachable. Attracting signal to highly-expressed nodes constrains RWR propagation to biologically active pathways in the liver. All other RWR parameters were identical. Random seed: 42.

244 **4.8 Quantifying perturbation efficiency**

245 By defining the restart vector as $\mathbf{p}_0(i) = 1/|T|$ (Eq. 75), the total steady-state probability mass \mathbf{p} is inherently
246 partitioned among the target set. Consequently, the summed influence I on the DILI module (Eq. 81) represents
247 the average perturbation efficiency per target. This normalization serves as an effect-size adjustment that allows
248 for a direct comparison of the per-unit impact of compounds with asymmetric target sets. Hereafter, we refer to
249 this as the perturbation efficiency.

250 **4.9 Bootstrap sensitivity analysis**

251 To assess whether target count explains the observed ranking: 100 random 10-target subsets were sampled without
252 replacement from Quercetin's 62-target pool. Each subset was scored by standard RWR. Summary statistics: mean,
253 standard deviation, 95th percentile. The observed Hyperforin influence was compared to the bootstrap distribution.
254 Random seed: 42.

255 **4.10 Chemical similarity analysis**

256 Structural similarity to known hepatotoxins was assessed to exclude confounding by chemical class. Morgan
257 fingerprints (ECFP4; radius = 2, 2048 bits) were generated using RDKit v2023.03 [18]. Reference set: DILrank
258 2.0 drugs with retrievable SMILES (542 DILI-positive, 365 DILI-negative). SMILES were retrieved via PubChem
259 REST API. Tanimoto coefficient:

$$\text{Tanimoto}(A, B) = \frac{|A \cap B|}{|A \cup B|} \quad (5)$$

260 Maximum similarity across the reference set was reported for each compound. Structural analog threshold: Tani-
261 moto > 0.4 [19].

262 **4.11 Software and reproducibility**

263 Python 3.10, NetworkX 3.1 [17]; R 4.3, igraph 1.5. All random seeds fixed at 42. Target lists sorted alphabetically
264 before processing.

265 **4.12 Code and data availability**

266 All code: <https://github.com/antonybevan/h-perforatum-network-tox>

267 Data sources:

368 **Figure Legends**

369 **Figure 1. Network context: target count and physical proximity to DILI genes.** (A) Target count in the
370 liver-expressed largest connected component. Quercetin: 62 targets; Hyperforin: 10 targets. (B) Shortest-path
371 proximity (d_c) to 82 DILI-associated genes. Hyperforin is physically closer ($d_c = 1.30$) than Quercetin ($d_c = 1.68$).
372 Z-scores represent deviation from degree-matched null expectation ($n = 1,000$ permutations). Quercetin: $Z =$
373 -5.44 ($p < 0.001$); Hyperforin: $Z = -3.86$ ($p < 0.001$). Negative Z-scores indicate closer-than-random proximity.
374 Network: STRING v12.0 (confidence ≥ 900), GTEx v8 (liver TPM ≥ 1).

375 **Figure 2. Instability of proximity Z-scores.** Dumbbell plot showing the dissociation between shortest-path
376 proximity (left) and random walk influence (right) at STRING confidence ≥ 900 . At this threshold, Quercetin
377 appears more "significant" in Z-score but is physically more distant (1.68 vs 1.30) from DILI genes. Hyperforin:
378 proximity $Z = -3.86$, influence $Z = +10.12$ ($p < 0.001$). Quercetin: proximity $Z = -5.44$, influence $Z = +4.55$
379 ($p < 0.001$). Influence quantified by random walk with restart (RWR; $\alpha = 0.15$). $n = 1,000$ degree-matched
380 permutations per compound.

381 **Figure 3. Expression weighting refines influence propagation.** Waterfall decomposition of Z-score changes
382 under expression-weighted influence (EWI). Initial Hyperforin advantage: $\Delta Z = +5.57$ (RWR). Hyperforin change:
383 -1.14 (attenuation of signal through liver-active hubs). Quercetin change: $+1.24$ (gain from high-expression
384 nodes like CFB). Residual Hyperforin advantage: $\Delta Z = +3.19$. Both compounds remain significant under EWI:
385 Hyperforin $Z = +8.98$ ($p < 0.001$); Quercetin $Z = +5.79$ ($p < 0.001$). Expression weighting from GTEx v8 liver
386 tissue.

387 **Figure 4. Average network influence quantifies efficiency disparity.** Phase plot of total influence versus
388 target count. Horizontal lines represent efficiency tiers (Efficiency/average influence = constant). Hyperforin
389 occupies a higher efficiency region despite fewer targets. Efficiency/average influence values: Hyperforin = 0.1138
390 (RWR), 0.1330 (EWI); Quercetin = 0.0322 (RWR), 0.0493 (EWI). Efficiency difference: $3.7 \times$ (based on bootstrap
391 mean comparison). The observed influence represents an effect-size normalization (total steady-state mass on DILI
392 genes); no independent permutation test was performed.

393 **Figure 5. Bootstrap sensitivity analysis excludes target-count confounding.** Density distribution of RWR
394 influence scores from 100 random 10-target samples drawn from Quercetin's 62-target pool. Shaded region: 95%
395 confidence interval (0.0160–0.0542). Vertical line: Hyperforin observed influence (0.1138). Hyperforin exceeds
396 the entire bootstrap distribution ($3.7 \times$ fold vs. mean). This confirms that Hyperforin's advantage is not attributable
397 to favorable target count. Bootstrap is a robustness control; it does not provide independent statistical evidence.

398 **Figure 6. Chemical similarity control excludes structural confounding.** Maximum Tanimoto similarity to
399 DILrank reference drugs. Reference set: 542 DILI-positive, 365 DILI-negative drugs. Hyperforin: max = 0.15
400 (DILI+), 0.20 (DILI-). Quercetin: max = 0.21 (DILI+), 0.22 (DILI-). Dashed line: 0.4 threshold for structural
401 analog detection [19]. Neither compound is a structural analog of known hepatotoxins. This orthogonal analysis
402 excludes chemical class as an explanation for the observed network signal. Fingerprints: Morgan (ECFP4), radius
403 2, 2048 bits.

404 **Tables**

Table 1: Network metrics reveal the instability of proximity Z-scores. While Quercetin achieves more significant proximity Z-scores due to tighter null distributions, Hyperforin is physically closer (d_c) to DILI genes. Influence-based metrics resolve this confounding and stably prioritize Hyperforin. Network: STRING v12.0 LCC (confidence ≥ 900) filtered to liver-expressed genes.

Metric	Compound	Targets	Observed	Z	p	Efficiency
<i>Tier 1: Shortest-path proximity</i>						
	Hyperforin	10	$d_c = 1.30$	-3.86	< 0.001*	—
	Quercetin	62	$d_c = 1.68$	-5.44	< 0.001*	—
<i>Instability: Quercetin is physically more distant yet more "significant"</i>						
<i>Tier 2: Random walk influence (RWR)</i>						
	Hyperforin	10	0.1138	+10.12	< 0.001*	0.1138
	Quercetin	62	0.0322	+4.55	< 0.001	0.0322
<i>Resolution: Correctly prioritizes physical proximity and regulatory hub modulation</i>						
<i>Tier 3: Expression-weighted influence (EWI)</i>						
	Hyperforin	10	0.1330	+8.98	< 0.001*	0.1330
	Quercetin	62	0.0493	+5.79	< 0.001	0.0493

*At permutation floor (<1/1,000).

Efficiency = average influence per target; RWR = random walk with restart; EWI = expression-weighted influence; d_c = mean minimum shortest-path distance; DILI = drug-induced liver injury. All associations survived Benjamini–Hochberg FDR correction ($q < 0.05$).

Table 2: Average influence efficiency. Normalization to the total seeding mass quantifies the average influence per target. Hyperforin targets are 3.7-fold more efficient at perturbing the DILI module than Quercetin targets.

Analysis	Hyp. Eff.	Quer. Eff.	Eff. Ratio*	Rob. Ratio†
RWR (topology-only)	0.1138	0.0322	3.5×	3.7×
EWI (expression-weighted)	0.1330	0.0493	2.7×	2.8×

*Efficiency Ratio = Observed average influence ratio. †Robust Ratio = Observed influence / size-matched Bootstrap Mean (N=10). RWR = random walk with restart; EWI = expression-weighted influence.

Table 3: **Bootstrap sensitivity excludes target-count confounding.** Random 10-target subsets ($n = 100$) sampled without replacement from Quercetin’s 62-target pool. Hyperforin’s observed influence exceeds the entire bootstrap distribution.

Statistic	Value	Interpretation
Hyperforin observed	0.1138	Reference
Bootstrap mean	0.0308	Expected if targets equivalent
Bootstrap SD	0.0100	Sampling variability
Bootstrap 95% CI	[0.0160, 0.0542]	2.5th–97.5th percentile
Hyperforin / mean	3.7×	Effect size
Exceeds 95% CI?	Yes	Not attributable to sampling

Random seed: 42. Note: Bootstrap confirms robustness to target selection; it does not constitute independent inferential evidence.

Table 4: **Chemical similarity excludes structural confounding.** Neither compound resembles known hepatotoxins ($\text{Tanimoto} < 0.4$). Quercetin is more similar to DILI-positive drugs yet shows lower network influence.

Compound	Max Tanimoto (DILI+)	Max Tanimoto (DILI-)	Analog?*	Network rank
Hyperforin	0.154	0.202	No	1 (higher influence)
Quercetin	0.212	0.220	No	2 (lower influence)

*Analog threshold: $\text{Tanimoto} > 0.4$ (Maggiora et al., 2014). Morgan fingerprints (ECFP4, radius 2, 2048 bits). DILIRank: 542 DILI+, 365 DILI- drugs.

Table 5: **Hyperforin targets include regulatory hubs.** All 10 Hyperforin targets in the liver-expressed LCC, with liver expression (GTEx v8) and network degree. PXR (NR1I2) is the master regulator; CYP enzymes are downstream effectors.

Gene	Protein	TPM	Degree	Function	DILI link
NR1I2	PXR	43	28	Master regulator	Direct
CYP3A4	CYP3A4	335	89	Xenobiotic metabolism	Direct
CYP2C9	CYP2C9	434	76	Xenobiotic metabolism	Direct
CYP2B6	CYP2B6	125	42	Xenobiotic metabolism	Indirect
AKT1	PKB	33	312	Stress signaling	Indirect
ABCB1	P-gp	7	53	Drug efflux	Direct
ABCC2	MRP2	60	38	Drug efflux	Direct
ABCG2	BCRP	4	31	Drug efflux	Indirect
MMP2	MMP2	5	87	ECM remodeling	Indirect
MMP9	MMP9	1	94	ECM remodeling	Indirect

AKT1 is the highest-degree target (312 neighbors). Five of 10 targets (NR1I2, CYP3A4, CYP2C9, ABCB1, ABCC2) are directly connected to DILI genes. TPM = transcripts per million; DILI = drug-induced liver injury; LCC = largest connected component.

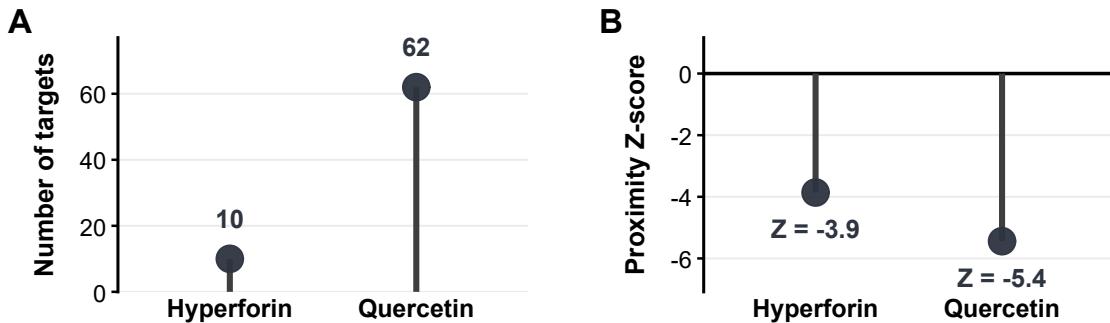

Table 6: **Influence ranking is robust to network construction parameters.** Hyperforin ranks first across all thresholds and influence metrics. Proximity Z-scores are unstable and reverse rankings between thresholds, failing to accurately reflect the physical distance advantage of Hyperforin.

Threshold	Compound	RWR Z	EWI Z	Proximity d_c	Proximity Z
≥ 700 (11,693 nodes)	Hyperforin	+12.08	+11.20	0.60	-6.04
	Quercetin	+5.53	+7.09	1.34	-5.46
≥ 900 (7,677 nodes)	Hyperforin	+10.12	+8.98	1.30	-3.86
	Quercetin	+4.55	+5.79	1.68	-5.44

Note: At ≥ 900 , Quercetin achieves a more "significant" proximity Z-score despite being physically more distant (1.68 vs 1.30) from DILI genes. RWR = random walk with restart; EWI = expression-weighted influence; d_c = mean minimum shortest-path distance; DILI = drug-induced liver injury.

405 **Figures**

Network context: target count and proximity to DILI genes

[DESCRIPTIVE CONTEXT] Target count and shortest-path proximity provide network context but are not used for causal inference. Proximity Z-scores represent deviation from degree-matched random expectation ($n = 1,000$ permutations). Negative values indicate closer-than-random proximity. Data: STRING v12.0 (≥ 900), human liver LCC.

Figure 1: **Network context: target count and physical proximity to DILI genes.** (A) Target count in the liver-expressed largest connected component. Quercetin: 62 targets; Hyperforin: 10 targets. (B) Shortest-path proximity (d_c) to 82 DILI-associated genes. Hyperforin is physically closer ($d_c = 1.30$) than Quercetin ($d_c = 1.68$). Z-scores represent deviation from degree-matched null expectation ($n = 1,000$ permutations). Quercetin: $Z = -5.44$ ($p < 0.001$); Hyperforin: $Z = -3.86$ ($p < 0.001$). Negative Z-scores indicate closer-than-random proximity. Network: STRING v12.0 (confidence ≥ 900), GTEx v8 (liver TPM ≥ 1).

Proximity does not predict influence

Proximity ranking is threshold-dependent; influence ranking is stable

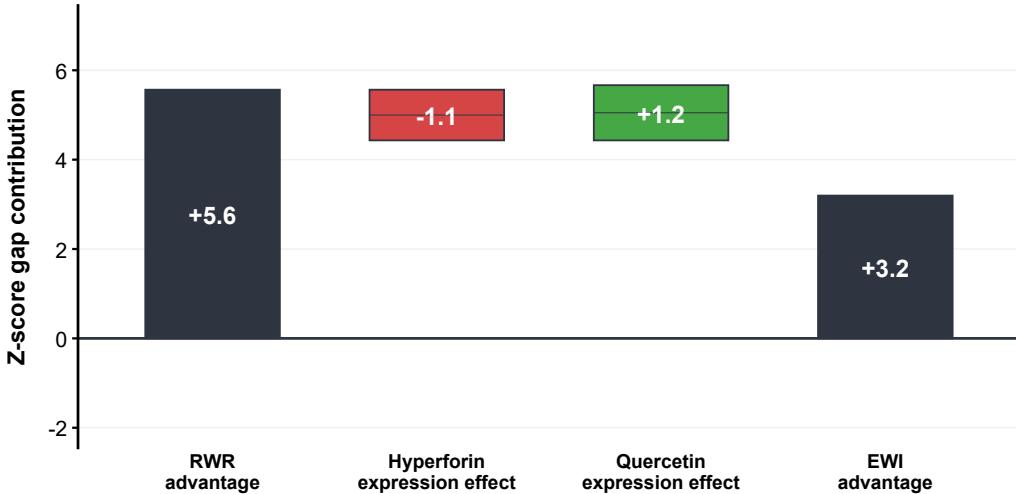

[CORE INFERENCE] The rank reversal demonstrates that shortest-path proximity does not predict functional influence. Lines connect each compound's proximity Z-score with its influence Z-score (random walk with restart, RWI). Both metrics derived from degree-matched permutation null models ($n = 1,000$). Data: STRING v12.0 (≥ 900).

Figure 2: **Instability of proximity Z-scores.** Dumbbell plot showing the dissociation between shortest-path proximity (left) and random walk influence (right) at STRING confidence ≥ 900 . At this threshold, Quercetin appears more "significant" in Z-score but is physically more distant (1.68 vs 1.30) from DILI genes. Hyperforin: proximity $Z = -3.86$, influence $Z = +10.12$ ($p < 0.001$). Quercetin: proximity $Z = -5.44$, influence $Z = +4.55$ ($p < 0.001$). Influence quantified by random walk with restart (RWR; $\alpha = 0.15$). $n = 1,000$ degree-matched permutations per compound.

Expression weighting attenuates but does not reverse the advantage

Gap: +5.6 (RWR) → +3.2 (EWI)

[CONSTRAINT ANALYSIS] The RWR advantage (+5.6) is partitioned under expression-weighted influence propagation:
 (1) Hyperforin's change under expression weighting (-1.1); (2) Quercetin's gain (+1.2, driven by CFB at 1115
 TPM). Residual advantage (+3.2) remains significant (both $p < 10^{-8}$). GTEx v8 liver expression (TPM ≥ 1). STRING
 v12.0 (≥ 900), $n = 1,000$ degree-matched permutations.

Figure 3: Expression weighting refines influence propagation. Waterfall decomposition of Z-score changes under expression-weighted influence (EWI). Initial Hyperforin advantage: $\Delta Z = +5.57$ (RWR). Hyperforin change: -1.14 (attenuation of signal through liver-active hubs). Quercetin change: $+1.24$ (gain from high-expression nodes like CFB). Residual Hyperforin advantage: $\Delta Z = +3.19$. Both compounds remain significant under EWI: Hyperforin $Z = +8.98$ ($p < 0.001$); Quercetin $Z = +5.79$ ($p < 0.001$). Expression weighting from GTEx v8 liver tissue.

Average network influence quantifies perturbation efficiency

Normalization reframes polypharmacology as efficiency, not coverage

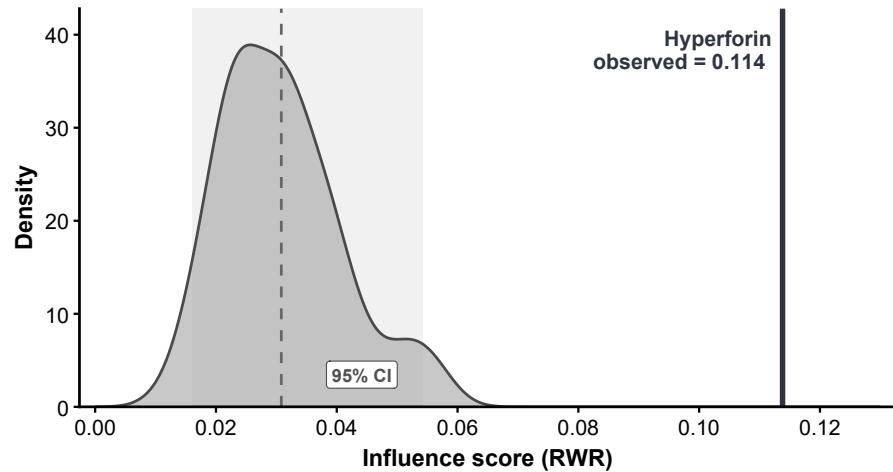

Average influence represents an effect-size normalization (total steady-state mass on DILI genes); no independent permutation test was performed. Horizontal lines represent efficiency tiers (Average Influence = constant). Hyperforin occupies a higher efficiency region despite fewer targets. Data: STRING v12.0 (≥ 900), $n = 1,000$ permutations.

Figure 4: Average network influence quantifies efficiency disparity. Phase plot of total influence versus target count. Horizontal lines represent efficiency tiers (Efficiency/average influence = constant). Hyperforin occupies a higher efficiency region despite fewer targets. Efficiency/average influence values: Hyperforin = 0.1138 (RWR), 0.1330 (EWI); Quercetin = 0.0322 (RWR), 0.0493 (EWI). Efficiency difference: **3.7 \times** (based on bootstrap mean comparison). The observed influence represents an effect-size normalization (total steady-state mass on DILI genes); no independent permutation test was performed.

Bootstrap sensitivity analysis excludes target-count confounding

Distribution of influence scores from random 10-target samples

[ROBUSTNESS CONTROL] Bootstrap sensitivity: 100 random 10-target samples from Quercetin's pool, scored by random walk with restart (RWI). Shaded = 95% CI. Hyperforin (solid line) exceeds entire distribution. Data: STRING v12.0 (≥ 900).

Figure 5: **Bootstrap sensitivity analysis excludes target-count confounding.** Density distribution of RWR influence scores from 100 random 10-target samples drawn from Quercetin's 62-target pool. Shaded region: 95% confidence interval (0.0160–0.0542). Vertical line: Hyperforin observed influence (0.1138). Hyperforin exceeds the entire bootstrap distribution (3.7× fold vs. mean). This confirms that Hyperforin's advantage is not attributable to favorable target count. Bootstrap is a robustness control; it does not provide independent statistical evidence.

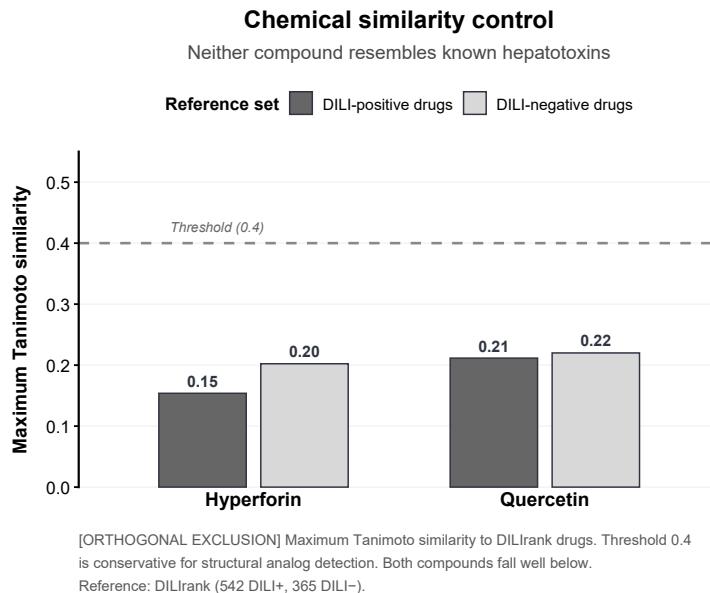

Figure 6: Chemical similarity control excludes structural confounding. Maximum Tanimoto similarity to DILIrack reference drugs. Reference set: 542 DILI-positive, 365 DILI-negative drugs. Hyperforin: max = 0.15 (DILI+), 0.20 (DILI-). Quercetin: max = 0.21 (DILI+), 0.22 (DILI-). Dashed line: 0.4 threshold for structural analog detection [19]. Neither compound is a structural analog of known hepatotoxins. This orthogonal analysis excludes chemical class as an explanation for the observed network signal. Fingerprints: Morgan (ECFP4), radius 2, 2048 bits.

ABCG2	ABCC2	1	Drug transport
ABCC2	NR1I2, ABCB1	2	Drug transport
MMP2	MMP9, SPP1	2	ECM remodeling
Total unique		12	

Table 12: **Table S6. Quercetin direct DILI gene connectivity summary.** Summary statistics for first-order DILI connections across Quercetin's 62 targets.

Metric	Value
Total targets in LCC	62
Targets with ≥ 1 direct DILI neighbor	18
Total direct DILI connections	31
Mean DILI neighbors per target	0.50
<i>Hyperforin comparison:</i>	
Hyperforin targets with ≥ 1 DILI neighbor	10/10 (100%)
Mean DILI neighbors per Hyperforin target	2.4

Table 13: **Table S7. Quercetin target genes in the liver-expressed network.** All 62 Quercetin targets in STRING v12.0 LCC (confidence ≥ 900) with liver TPM ≥ 1 (GTEX v8). Sorted by descending liver expression.

Gene	TPM	Gene	TPM	Gene	TPM	Gene	TPM
CFB	1115	CYP3A4	335	FN1	229	ALDH2	183
ANPEP	160	PPIA	112	SERPINA5	104	CYP1A2	72
CA2	64	APP	63	PYGL	55	HDAC6	45
ESRRRA	42	MAOA	35	AKR1C2	33	AKT1	33
CTSH	28	XDH	26	CHRNA4	25	PIK3R1	24
PIM1	24	LDLR	23	EGFR	17	ELOVL1	18

SNX18	SOD1	SOD3	SPP1	TALDO1	TBXA2R	TCTN1	TF
TTR	UGT1A9						

Table 15: **Table S9. Null distribution parameters from permutation testing.** Null distribution parameters (mean and standard deviation) from $n = 1,000$ degree-matched permutations. Note the tightening of the Quercetin null distribution as the number of targets increases, which drives the inflation of proximity Z-scores.

Metric	Compound	μ_{null}	σ_{null}	x_{obs}	Z-score
<i>Shortest-path proximity (at ≥ 900)</i>					
	Hyperforin (10)	2.21	0.235	1.30	-3.86
	Quercetin (62)	2.17	0.091	1.68	-5.44
<i>Random walk influence (at ≥ 900)</i>					
	Hyperforin (10)	0.0147	0.0098	0.1138	+10.12
	Quercetin (62)	0.0148	0.0038	0.0322	+4.55
<i>Expression-weighted influence (at ≥ 900)</i>					
	Hyperforin (10)	0.0205	0.0125	0.1330	+8.98*
	Quercetin (62)	0.0209	0.0049	0.0493	+5.79*

*Significance remains high despite tissue-specific attenuation. μ_{null} = null distribution mean; σ_{null} = null distribution standard deviation; x_{obs} = observed metric value.
